1. Attribute B has two branches which are 0 and 1. Both branches have a ½ chance and the attribute B impurity is 0 when we calculate the $\log_2$. Since the class labels are determinate after the first split, we don't need to use the attribute A. So our tree would have attribute B as its root and if the value for attribute B is 0 then the result is 1, or yes, and if attribute B is 1, then the result is 0, or no.
2. B, C, D
3. The linear SVM cannot accurately represent non-linear data like a kernel SVM can
4. She could use a decision tree. The labeled data means we can evaluate different features of personal information and make splits to create a decision tree that minimize impurity.
